A biohybrid strategy for enabling photoredox catalysis with low-energy light

Photocatalysts convert light into potent reactivity. Here, we report a biohybrid catalyst in which a photosynthetic protein performs broad-spectrum light absorption and subsequent energy transfer to a conjugated photocatalyst, leading to improved yields in test reactions. This strategy has the potential to be generalized for applications in industrial and biological catalysis.

SUMMARY
Natural systems drive the high-energy reactions of photosynthesis with efficient and broadband energy capture. Transition-metal photocatalysts similarly convert light into chemical reactivity, and yet suffer from light-limited operation and require blue-to-UV excitation. In photosynthesis, both light capture and reactivity have been optimized by separation into distinct sites. Inspired by this modular architecture, we synthesized a biohybrid photocatalyst by covalent attachment of the photosynthetic light-harvesting protein R-phycoerythrin (RPE) to the transition-metal photocatalyst tris(2,2'-bipyridine)ruthenium(II) ([Ru(bpy)3]2+). Spectroscopic investigation found that absorbed photoenergy was efficiently funneled from RPE to [Ru(bpy)3]2+. The utility of the biohybrid photocatalyst was demonstrated via an increase in yields for a thiol-ene coupling reaction and a cysteinyl-desulfurization reaction, including recovered reactivity at red wavelengths where [Ru(bpy)3]2+ alone does not absorb.

INTRODUCTION
Photoredox catalysis harnesses light energy to afford potent reactivity to a broad range of chemistries and substrates that are otherwise unreactive. Upon visible excitation, the photocatalyst is transformed into a high-energy reactive intermediate that can be used to promote challenging or previously elusive transformations.1–4 The reactivity is most often ascribed to electron or energy transfer from long-lived triplet metal-to-ligand charge-transfer (3MLCT) states that generate potent reductants or oxidants.5,6 For example, transition-metal photoredox catalysts have been used for many carbon–carbon bond formations that have been instrumental in the development of pharmaceuticals, agrochemicals, and complex natural products.7–13 Despite their catalytic utility, the charge transfer and other reactive states are limited by small absorption bandwidths (∼100 nm) and low molar absorptivities (10^2–10^4 M^-1 cm^-1), resulting in poor photon-conversion efficiency.1,14–17 Additionally, most transition-metal photoredox catalysts require excitation at high photon energies where the effective absorbance is often further reduced by secondary catalysts, substrates, or reagents that act as optical filters. The high-energy excitation can also cause cellular damage and so has limited the biological applications of this powerful technology.18–21

Nature overcomes the poor light-harvesting ability of the charge transfer and similar reactive states with dedicated machinery to capture sunlight for photosynthesis.22–27 Light-harvesting proteins absorb over large spectral bandwidths...
> (~250 nm) with high molar absorptivities (~10⁶ M⁻¹ cm⁻¹), and then efficiently transfer this energy to sensitize neighboring proteins that contain the reactive site. Inspired by the modularity found in biology, several types of photocatalysts have been produced that employ a similar approach. However, the stringent distance dependence requirements and nonspecific reactivity of electron transfer create additional synthetic and operational challenges. Energy transfer, which occurs over longer distances, was introduced by conjugating together transition-metal photocatalysts with different excitation energies, which expanded their absorption window. Despite the expanded absorption, the low extinction coefficients of the photocatalysts lead to light-limited activity under many conditions. The absorption range was also expanded into the low-energy (near-infrared) region by direct excitation of the ³MLCT state, and the utility of this scheme was demonstrated on a range of photoredox reactions. However, the extremely low molar absorptivity (~10² M⁻¹ cm⁻¹) of this state limits its light-harvesting ability. Upconversion of triplet states in a sensitizer/photocatalyst mixture was introduced as an alternative strategy to use near-infrared light, but with low photon conversion efficiency. Finally, sensitization of a transition-metal photoredox catalyst through energy transfer from light-harvesting ligands was demonstrated, but its impact on reactivity was not investigated.

Here, we mimicked the design found in photosynthesis by conjugating the prototypical transition-metal photocatalyst, tris(2,2'-bipyridine)ruthenium(II) ([Ru(bpy)₃]²⁺), to the commercially available, photosynthetic light-harvesting protein, R-phycoerythrin (RPE), from red algae (Figure 1). The resultant biohybrid, henceforth referred to as RPE-(Ru)ₙ, absorbed at wavelengths up to 630 nm and transferred energy from RPE to [Ru(bpy)₃]²⁺. The energy capture provided by the light harvester enhanced catalytic yields by a factor of 10 as compared with controls that lacked light-harvesting for two representative reactions, a radical thiol-ene coupling and a cysteinyl desulfurization.

### RESULTS AND DISCUSSION

#### Biohybrid synthesis and steady-state characterization

Synthesis of the biohybrid construct shown in Figure 1A (right) was accomplished by taking advantage of the 72 surface-exposed lysine residues on RPE identified using Py-mol (Section S3A). Conjugation of [Ru(bpy)₃]²⁺ to the lysine side chains occurred readily upon treatment of RPE with a derivative of [Ru(bpy)₃]²⁺ substituted with an N-hydroxysuccinimide (NHS) ester (Figure S1). While conjugation to other amino acids is possible, the lysines are the most likely site due to the nucleophilicity of the amine group and their propensity for exterior positioning. They are primarily evenly dispersed across the surface of the outer ring of the protein with two per subunit on the ends of the cylinder-like structure (Figure S10), likely leading to stochastic decoration of the exterior of RPE with [Ru(bpy)₃]²⁺. The NHS ester derivative of [Ru(bpy)₃]²⁺ was chosen as the catalyst because of its commercial availability and the historical prevalence of [Ru(bpy)₃]²⁺. Purification by centrifugal filtration and fast protein liquid chromatography (FPLC) afforded the hybrid in high purity (Section S1).

Intact mass spectrometry (MS) data were obtained for both free RPE and purified RPE-(Ru)ₙ to confirm conjugation (Figure S7). RPE is a hexameric protein in which alpha (α) and beta (β) subunits form an (αβ)₃ quaternary structure. The MS of RPE showed the α and β subunits at masses of 18,889 Da and 20,308 Da, respectively, both in agreement with the literature. Compared with free RPE, RPE-(Ru)ₙ...
exhibited modifications of 610 Da in its mass spectrum, corresponding to the molecular weight of the [Ru(bpy)$_3$]$_{2+}$ catalyst. The $\alpha$ subunit showed equally abundant peaks (1:1:1) for no modification, one modification, and two modifications. The $\beta$ subunit showed unequally abundant peaks (1:1:0.2) for no modification, one modification, and two modifications, respectively. A weighted average of these data was used to estimate that ten [Ru(bpy)$_3$]$_{2+}$ catalysts per one RPE were retained under the MS conditions.

The absorption and emission spectra of the conjugated hybrid are overlaid with its individual components in Figure 2A. RPE-(Ru)$_n$ had an absorption spectrum similar to the free protein due to the significantly larger molar absorptivity coefficient ($10^2$ times) of RPE compared with [Ru(bpy)$_3$]$_{2+}$. The similar profile of the absorption spectra before and after conjugation also confirmed that the integrity of the protein was maintained. As expected, RPE-(Ru)$_n$ showed additional absorbance in the region around the [Ru(bpy)$_3$]$_{2+}$ MLCT states centered at 459 nm. Additionally, the peak in the RPE-(Ru)$_n$ spectrum corresponding to the energy of the [Ru(bpy)$_3$]$_{2+}$ pyridine ligand $\pi \rightarrow \pi^*$ transition (285 nm) increased in intensity relative to the free protein (Figure S8). Finally, the sum of the component spectra matched well with the spectrum of the purified RPE-(Ru)$_n$ with a 1:8 ratio, similar to the results from MS and confirming conjugation (Figure S8).

The steady-state fluorescence emission spectra of free RPE and RPE-(Ru)$_n$ are also shown in Figure 2A. The spectral profiles were essentially the same due to the much lower level of photoluminescence emission from [Ru(bpy)$_3$]$_{2+}$. The integrated
fluorescence intensity decreased by \( \sim 60\% \) for RPE-(Ru)\( _n \) compared with RPE, providing further evidence of successful conjugation and indicating the presence of energy transfer.

**Characterization of the excited-state dynamics**

Time-resolved spectroscopy was used to characterize the photophysics of the biohybrid. The fluorescence lifetime was measured for both the free protein and biohybrid structure. The RPE fluorescence emission (Figure 2B) showed a monoexponential decay with a timescale of 2.63 ns, in agreement with literature values of 2.3–3.1 ns.\(^{28,29}\) In contrast, the RPE-(Ru)\( _n \) emission showed a multiexponential decay profile, which was best fit with a triexponential function. The two fast timescales were \( \sim 0.039 \) and \( \sim 0.368 \) ns, each with an amplitude of \( \sim 40\% \). The slower timescale was 1.70 ns. The average lifetime was 0.384 ns, which gave an overall energy-transfer efficiency of 85\%. The fitting parameters for all samples are summarized in Tables S2 and S3. As discussed above, although each RPE-(Ru)\( _n \) contains on average ten \([\text{Ru(bpy)}_3]^{2+}\), the sample is a heterogeneous mixture with \([\text{Ru(bpy)}_3]^{2+}\) attached to RPE in a variety of stoichiometries and conjugation sites. We assign the two fast timescales to uphill energy transfer from RPE to \([\text{Ru(bpy)}_3]^{2+}\) in RPE-(Ru)\( _n \) with a large number of conjugated \([\text{Ru(bpy)}_3]^{2+}\) and/or \([\text{Ru(bpy)}_3]^{2+}\) well-positioned for energy transfer. Consistent with this assignment, the timescale of energy transfer for RPE-(Ru)\( _n \) with ten \([\text{Ru(bpy)}_3]^{2+}\) was calculated to be 0.409 ns using Förster theory (Section S3). These calculations also predict a 78\% energy transfer efficiency, close to the experimental value. Förster energy transfer is governed by the spectral overlap and distance between the donor and acceptor. Due to the small spectral overlap, each energy transfer pathway is inefficient. However, they give an overall high energy transfer efficiency from the combined contributions of the ten energy transfer pathways from RPE to \([\text{Ru(bpy)}_3]^{2+}\) (Section S3B). Despite the uphill nature of the energy-transfer step, rapid trapping of the excitation by intersystem crossing on \([\text{Ru(bpy)}_3]^{2+}\) likely limited back transfer. We assign the slow timescale to energy transfer in the small population of RPE-(Ru)\( _n \), bearing only conjugated \([\text{Ru(bpy)}_3]^{2+}\) that are poorly positioned for energy transfer.

Transient absorption (TA) spectroscopy was used to monitor the excited-state dynamics, including transitions into nonemissive states. To probe the photophysical pathways with high temporal resolution, ultrafast TA measurements were performed on both RPE and RPE-(Ru)\( _n \) with excitation at 540 nm, which overlaps with the RPE absorption peak. For free RPE (Figure 3A, left), initial excitation gave rise to a ground...
state bleach (GSB)/stimulated emission (SE) signal across the absorption spectrum. As shown in Figure 3B, the GSB/SE signal at the low energy state of RPE decayed on 54 ps and 2.2 ns (1.56 ns average) timescales, similar to previously observed values.28 For RPE-(Ru)n (Figure 3A, right), the GSB/SE signal decayed more quickly across the spectrum, likely as a result of energy transfer to [Ru(bpy)3]2+. As shown in Figure 3B, the signal at the low-energy state decayed on 36 and 170 ps (137 ps average lifetime) timescales, consistent with the fluorescence lifetime measurements and calculations of the energy transfer timescale from RPE to [Ru(bpy)3]2+.

To more directly probe [Ru(bpy)3]2+ sensitization upon RPE excitation, we employed nanosecond TA spectroscopy on RPE-(Ru)n, [Ru(bpy)3]2+, and an unconjugated mixture of RPE and [Ru(bpy)3]2+. The prompt transient spectra are shown for all three samples in Figure 3C. For [Ru(bpy)3]2+ excited at 450 nm, the characteristic GSB at 450 nm and excited state absorption at 380 nm were observed, consistent with previous reports.69 For the unconjugated mixture, after excitation of RPE at 540 nm, a component of the RPE GSB/SE persisted while spectral features of excited [Ru(bpy)3]2+ were absent. For the RPE-(Ru)n conjugate, a similar GSB/SE component was present in the RPE spectral region, but the spectral features of [Ru(bpy)3]2+ also appeared, signaling successful energy transfer to the photocatalyst. Excitation further toward the red, at 580 nm, also demonstrated energy transfer to the photocatalyst (Figure S22). Energy transfer is expected to populate the charge-transfer bands of [Ru(bpy)3]2+ almost exclusively for excitation wavelengths above 500 nm, as the catalytically deleterious triplet metal-centered state is higher in energy.55,70 Although these experiments provide spectral evidence that energy transfer occurs,
the signals of energy transfer appear within the 8-ns instrument response function (IRF), so the timescale of energy transfer cannot be discerned from this experiment (Section S4C). These results do, however, provide direct experimental evidence of the assignment to energy transfer, as electron transfer would have resulted in the spectra of the oxidized or reduced form of [Ru(bpy)3]2+ in the RPE-(Ru)n sample.44

Demonstration of enhanced catalysis using the biohybrid

To establish the catalytic ability of RPE-(Ru)n, we assessed product yields for two radical initiation reactions previously reported in literature, a thiol-ene coupling and a cysteinyl desulfurization.71,72 The goal of this proof-of-concept study is to identify an enhancement in catalytic performance and, for radical chain reactions, differences in the photodriven initiator formation can be easily observed in the final product yields. While the sequential nature of the propagation means that the improvement in the photodriven process cannot be straightforwardly quantified, these reactions allow for clear qualitative comparison of yields. Performance in the presence of RPE-(Ru)n was compared with [Ru(bpy)3]2+, RPE, and an unconjugated mixture of RPE and [Ru(bpy)3]2+ as controls at three LED wavelengths (blue, 459 nm; green, 513 nm; red, 630 nm). Full experimental details, including all yields, substrates, and product NMR characterization are included in Sections S5 and S6.

We first investigated the effectiveness of RPE-(Ru)n in the thiol-ene reaction, a widely adopted bioconjugation strategy extended to photoredox catalysis by Yoon and co-workers.71,73,74 Relative to small molecule [Ru(bpy)3]2+, coupling of glutathione (1) and allyl alcohol (3) under RPE-(Ru)n, catalysis presented improved yields under red, green, and blue-light irradiation (Figure 4; Section S5). Most notably, RPE-(Ru)n afforded product 2 in 89% yield under red-light irradiation, whereas no product formation was observed with [Ru(bpy)3]2+. Under green irradiation, which corresponds to the maximum of the RPE absorbance, 2 was generated in ~10% yield with [Ru(bpy)3]2+ alone and with the unconjugated [Ru(bpy)3]2+ and RPE mixture. By contrast, RPE-(Ru)n catalyzed the reaction in 70% yield. The yields with RPE-(Ru)n under both green and red irradiation were higher than the yield with [Ru(bpy)3]2+ alone under blue irradiation at the maximum of its absorbance (10%, in agreement with previous literature.

Figure 4. Photocatalytic radical thiol-ene reaction

RPE-(Ru)n enables or enhances yields at red and green wavelengths. Reaction times are 2 h except where noted. *12 h reaction time. Note: “equiv of Ru” refers to the fact that all reactions were performed with catalyst loadings normalized to [Ru(bpy)3]2+.44
reports\(^4\). To demonstrate the generality of the observed enhancement, four additional substrates (4–7) were evaluated. In all cases, product yields under green or red irradiation surpassed yields achieved by [Ru(bpy)\(_3\)]\(^{2+}\) alone or by the unconjugated [Ru(bpy)\(_3\)]\(^{2+}\)/RPE mixture, even reaching quantitative yields for glycosylation (7). The ability to catalyze the reaction at red wavelengths is afforded by uphill energy transfer utilizing thermal energy to account for differences in activation energy (Section S3C).\(^75,76\) Furthermore, both product yields and photostability of RPE-(Ru)\(_n\) increased under low irradiance, indicating that optimal operation may require the photon absorption rate to be empirically matched to the catalytic cycle. These results demonstrate the ability of RPE-(Ru)\(_n\) to improve catalytic performance and enable operation under irradiation at any visible wavelength.

To determine the versatility of our RPE-(Ru)\(_n\), we also investigated its performance in a cysteinyl-desulfurization method developed by Guo and co-workers in 2016.\(^72\) The original reaction, which employs 5 mol % of [Ru(bpy)\(_3\)]\(^{2+}\), converted glutathione (1) to product 8 with 85% yield under blue-light irradiation. With our RPE-(Ru)\(_n\) biohybrid, the desulfurization proceeds with similarly high efficiencies under red- or green-light irradiation (78% and 100%, respectively) using 0.3 mol % of the catalyst. Notably, control reactions with [Ru(bpy)\(_3\)]\(^{2+}\), RPE, or the unconjugated mixture of the two species showed no reactivity across both irradiation wavelengths (Figure 5). The reduced catalyst loading of 0.3 mol % under conditions relevant to this study, compared with the previously reported value of 5 mol %, also demonstrates the synthetic competency of the biohybrid.\(^72\) Furthermore, the large RPE appendage with a mass of 240 kDa allowed for facile catalyst recovery through centrifugal filtration with a 50 kDa molecular weight cut-off (MWCO) filter. Biohybrid reusability was screened by resubjecting RPE-(Ru)\(_n\) to fresh reagents, affording 83% yield under red-light irradiation.

**Conclusion**

A biohybrid catalyst consisting of the photosynthetic light-harvesting protein RPE and multiple conjugated [Ru(bpy)$_3$]$^{2+}$ photocatalysts has been synthesized, characterized, and shown to improve catalytic efficiency. Energy transfer from RPE to [Ru(bpy)$_3$]$^{2+}$ improved yields and enabled reactivity even at red wavelengths. The biohybrid photocatalyst is also environmentally sustainable as it operates in aqueous conditions, exhibits activity under low-energy irradiation, and is easily reused. These initial demonstrations lay the groundwork for the development of photocatalysts with distinct light-harvesting and reactive components as seen in photosynthesis, which, as illustrated here, allows robust and reliable reactivity.

**EXPERIMENTAL PROCEDURES**

**Resource availability**

**Lead contact**

Further information and requests for resources should be directed to and will be fulfilled by the lead contact, Gabriela S. Schlau-Cohen (gssc@mit.edu).

**Materials availability**

All materials generated in this study are available from the lead contact upon request.

**Data and code availability**

Data and code generated during this study are available from the lead contact upon request.

**Sample preparation**

R-phycoerythrin (RPE; Agilent, Cat. No. PB-32) was dialyzed against phosphate buffer (0.1 M sodium phosphate, pH = 7.5, filter sterilized and degassed) and refrigerated until needed. Bis(2,2'-bipyridine)-4'-methyl-4-carboxybipyridine-ruthenium (II) N-succinimidyl ester bis(hexafluorophosphate) ([Ru(bpy)$_3$]$^{2+}$-NHS ester, Sigma-Aldrich Cat. No. 96631) and dimethyl sulfoxide (DMSO) were used as received. Bioconjugation of the [Ru(bpy)$_3$]$^{2+}$-NHS ester to RPE was performed by reacting RPE (250 μL of 1 mg/mL in phosphate buffer) with [Ru(bpy)$_3$]$^{2+}$-NHS ester (50 μL of 20 mg/mL in DMSO, ~950× molar excess of catalyst). Multiple small-scale (300 μL) reactions were performed in parallel to allow [Ru(bpy)$_3$]$^{2+}$-NHS ester to easily mix with phycobiliproteins without hydrolysis of the NHS ester. The reaction mixtures were placed on an incubator shaker (1,100 rpm) at room temperature for 1 h. After incubation, the small-scale reaction mixtures were combined, placed into a 50 kDa MWCO centrifugal filter (Millipore, Cat. No. UFC9050) and centrifuged at 4°C and 4,000 rpm (3,220 rcf) for 15–20 min. Further purification was performed using FPLC with a NGC chromatography system (Bio-Rad) on a Superose® 6 10/300 GL column (Cytiva Life Sciences) at a flow rate of 0.5–0.75 mL/min at 4°C in phosphate buffer. Fractions of the peak eluting at 16.2 mL for RPE were collected and centrifuge concentrated using the same parameters as described above. All reactions and spectroscopic studies were performed in phosphate buffer (0.1 M sodium phosphate, pH = 7.5, filter sterilized and degassed). Further details on conjugation and purification are provided in Section S1.

**Steady-state absorption and fluorescence measurements**

Linear absorbance spectra were acquired using a Shimadzu UV-2401PC spectrophotometer. Fluorescence emission spectra were obtained using a Varian Cary Eclipse with 565 nm excitation at the maximum absorbance of RPE.
**Fluorescence lifetime measurements**

Fluorescence lifetime measurements were performed using a supercontinuum generated in a nonlinear photonic crystal fiber (FemtoWhite 800, NKT photonics) pumped by a Ti:sapphire oscillator (Mai Tai, Spectra Physics). Full details on the laser setup are in Section S4. The excitation wavelength was selected using a 550 nm, 15 nm FWHM bandpass filter (Chroma Technology Corp ET550/15x) and the emission wavelength was selected using a 580 nm, 10 nm FWHM bandpass filter (Thor Labs FB580-10). The excitation laser pulse was focused on a 1 cm × 2 mm pathlength quartz cuvette (Hellma Analytics 108.002F-QS) to a spot size of 0.66 μm² and with a pulse energy of 0.027 nJ per pulse. The IRF was measured using a scatter solution containing a 1:100 v:v mixture of HS-40 colloidal silica (Sigma-Aldrich) and phosphate buffer with a width of 75–95 ps (FWHM). Fluorescence lifetime decay curves were individually fitted to a mono- or triexponential function using iterative reconvolution with the IRF.

**Intact mass spectrometry (intact MS)**

RPE and RPE-(Ru)ₙ were loaded onto a Thermo MAbPac reversed phase column using an Agilent1100 HPLC system. Further details on chromatography elution parameters can be found in Section S2A. MS data were acquired in profile mode with a Thermo Q Exactive mass spectrometer at 17,000 resolution and analyzed using ThermoBioPharma Finder™ 3.2 ReSpect with default settings.

**Transient absorption (TA) studies**

Femtosecond TA studies were conducted using a broadband white light source, the complete details of which are described in Section S4B. Briefly, pulses were obtained by using the output of a Ti:sapphire regenerative amplifier (Coherent Libra, 5 kHz, 1.1 mJ, 40 fs pulse, λₑ=800 nm). White light was generated using an argon gas chamber (20 psi) and filtered for a center wavelength of 540 nm. Spectra were collected by measuring the probe laser for each pulse using a line CCD (e2v) and chopping the pump laser at 2.5 kHz. Samples were prepared at an optical density of 0.3 in a 1 mm path cuvette, flowed with a peristaltic pump to prevent photodegradation and re-excitation, and chilled to 8°C throughout the measurement. Linear absorption spectra were collected before and after TA to confirm sample integrity was retained.

Nanosecond TA spectra were acquired on a Edinburgh Instruments LP 920 spectrometer outfitted with a liquid nitrogen equipped temperature controller (Unisoku CoolSpeK). Samples were excited using the output of a tunable OPO (Opotek Vibrant 355) operating at 1 Hz. The excitation source was kept to less than 2.5 mJ/pulse (~5 mJ/cm²). The probe source of the LP 920 (a xenon arc lamp) was also filtered through two long-pass filters (290 and 320 nm) to prevent the UV component of the probe light from degrading the sample. Samples were prepared in quartz 1 cm cuvettes with aqueous phosphate buffer solutions, stirred, and kept at 8°C for the duration of the experiment. To capture the transient absorption signals for the bound ruthenium chromophores, which have small excited-state-induced changes in molar absorptivity relative to the protein, sample absorbances of 0.6–0.9 at 565 nm were used. The pulse duration was 8 ns (see note in final paragraph of Section S4C).

**Synthetic reactions**

Thiol-ene coupling⁷¹ and cysteinyldesulfurization⁷² reactions were performed as described in the literature, with modifications due to the requirements of RPE-(Ru)ₙ. The reactions were performed in phosphate buffer, at the reduced scale.
dictated by the protein, without agitation to prevent aggregation, and with reduced light intensity due to the greater absorban ce of the protein. Reactions were repli-
cated and screened at three LED illuminations (blue, green, red) for the [Ru(bpy)3]2+, RPE, RPE-(Ru)n, and an unconjugated mixture of the two components, and examined for enhanced yields using 1H NMR against an external standard. Quantum yield mea-
urements were performed on both test reactions using ferrioxalate actinometry. We also screened RPE-(Ru)n reusability after recovery via size-exclusion centrifugal filtra-
tion. Full experimental details are described in Sections S5 and S6.
